# 1 Debugging mod\_perl C Internals

# **1.1 Description**

This document explains how to debug C code under mod\_perl, including mod\_perl core itself.

For certain debugging purposes you may find useful to read first the following notes on mod\_perl internals: Apache 2.0 Integration and mod\_perl-specific functionality flow.

# 1.2 Debug notes

META: needs more organization (if you grok any of the following, patches are welcome)

META: there is a new compile-time option in perl-5.8.8+: -DDEBUG\_LEAKING\_SCALARS, which prints out the addresses of leaked SVs and new\_SV() can be used to discover where those SVs were allocated. (see perlhack.pod for more info)

META: httpd has quite a lot of useful debug info: http://httpd.apache.org/dev/debugging.html (need to add this link to mp1 docs as well)

META: profiling: need a new entry of profiling. + running mod\_perl under gprof: Defining GPROF when compiling uses the moncontrol() function to disable gprof profiling in the parent, and enable it only for request processing in children (or in one\_process mode).

META: Jeff Trawick wrote a few useful debug modules, for httpd-2.1: mod\_backtrace (similar to bt in gdb, but doesn't require the core file) and mod\_whatkilledus (gives the info about the request that caused the segfault). http://httpd.apache.org/~trawick/exception\_hook.html

## 1.2.1 Entering Single Server Mode

Most of the time, when debugging Apache or mod\_perl, one needs to start Apache in a single server mode and not allow it to detach itself from the initial process. This is accomplished with:

```
% httpd -DONE_PROCESS -DNO_DETACH
```

## 1.2.2 Setting gdb Breakpoints with mod\_perl Built as DSO

If mod\_perl is built as a DSO module, you cannot set the breakpoint in the mod\_perl source files when the *httpd* program gets loaded into the debugger. The reason is simple: At this moment *httpd* has no idea about mod\_perl module yet. After the configuration file is processed and the mod\_perl DSO module is loaded then the breakpoints in the source of mod\_perl itself can be set.

The trick is to break at *apr\_dso\_load*, let it load *libmodperl.so*, then you can set breakpoints anywhere in the modperl code:

```
% gdb httpd
(gdb) b apr_dso_load
(gdb) run -DONE_PROCESS
[New Thread 1024 (LWP 1600)]
```

```
[Switching to Thread 1024 (LWP 1600)]
Breakpoint 1, apr_dso_load (res_handle=0xbfffb48c, path=0x81ladcc
    "/home/stas/apache.org/modperl-perlmodule/src/modules/perl/libmodperl.so",
    pool=0x80ela3c) at dso.c:138
141 void *os_handle = dlopen(path, RTLD_NOW | RTLD_GLOBAL);
(gdb) finish
...
Value returned is $1 = 0
(gdb) b modperl_hook_init
(gdb) continue
```

This example shows how to set a breakpoint at *modperl\_hook\_init*.

To automate things you can put those in the .gdb-jump-to-init file:

```
b apr_dso_load
run -DONE_PROCESS -d `pwd`/t -f `pwd`/t/conf/httpd.conf
finish
b modperl_hook_init
continue
```

and then start the debugger with:

```
% gdb /home/stas/httpd-2.0/bin/httpd -command \
'pwd'/t/.gdb-jump-to-init
```

## 1.2.3 Starting the Server Fast under gdb

When the server is started under gdb, it first loads the symbol tables of the dynamic libraries that it sees going to be used. Some versions of gdb may take ages to complete this task, which makes the debugging very irritating if you have to restart the server all the time and it doesn't happen immediately.

The trick is to set the auto-solib-add flag to 0:

```
set auto-solib-add 0
```

as early as possible in ~/.gdbinit file.

With this setting in effect, you can load only the needed dynamic libraries with *sharedlibrary* gdb command. Remember that in order to set a breakpoint and step through the code inside a certain dynamic library you have to load it first. For example consider this gdb commands file:

```
b modperl_hook_init
# start: modperl_hook_init
continue
# restart: ap_run_pre_config
continue
# restart: modperl_hook_init
continue
b apr_poll
continue
# load APR/PerlIO/PerlIO.so
sharedlibrary PerlIO
b PerlIOAPR_open
```

which can be used as:

% gdb -command=.gdb-commands

This script stops in *modperl\_hook\_init()*, so you can step through the mod\_perl startup. We had to use the *ap\_run\_pre\_config* so we can load the *libmodperl.so* library as explained earlier. Since httpd restarts on the start, we have to *continue* until we hit *modperl\_hook\_init* second time, where we can set the breakpoint at *apr\_poll*, the very point where httpd polls for new request and run again *continue* so it'll stop at *apr\_poll*. This particular script passes over modperl\_hook\_init(), since we run the continue command a few times to reach the *apr\_poll* breakpoint. See the Precooked gdb Startup Scripts section for standalone script examples.

When gdb stops at the function *apr\_poll* it's a time to start the client, that will issue a request that will exercise the server execution path we want to debug. For example to debug the implementation of APR::Pool we may run:

% t/TEST -run apr/pool

which will trigger the run of a handler in *t/response/TestAPR/pool.pm* which in turn tests the APR::Pool code.

But before that if we want to debug the server response we need to set breakpoints in the libraries we want to debug. For example if we want to debug the function PerlIOAPR\_open which resides in *APR/PerlIO/PerlIO.so* we first load it and then we can set a breakpoint in it. Notice that gdb may not be able to load a library if it wasn't referenced by any of the code. In this case we have to load this library at the server startup. In our example we load:

PerlModule APR::PerlIO

in *httpd.conf*. To check which libraries' symbol tables can be loaded in gdb, run (when the server has been started):

gdb> info sharedlibrary

which also shows which libraries are loaded already.

Also notice that you don't have to type the full path of the library when trying to load them, even a partial name will suffice. In our commands file example we have used sharedlibrary mod\_perl instead of saying sharedlibrary mod\_perl.so.

If you want to set breakpoints and step through the code in the Perl and APR core libraries you should load their appropriate libraries:

gdb> sharedlibrary libperl
gdb> sharedlibrary libapr
gdb> sharedlibrary libaprutil

Setting *auto-solib-add* to 0 makes the debugging process unusual, since originally gdb was loading the dynamic libraries automatically, whereas now it doesn't. This is the price one has to pay to get the debugger starting the program very fast. Hopefully the future versions of gdb will improve.

Just remember that if you try to *step-in* and debugger doesn't do anything, that means that the library the function is located in wasn't loaded. The solution is to create a commands file as explained in the beginning of this section and craft the startup script the way you need to avoid extra typing and mistakes when repeating the same debugging process again and again.

Under threaded mpms (e.g. worker), it's possible that you won't be able to debug unless you tell gdb to load the symbols from the threads library. So for example if on your OS that library is called *libpthread.so* make sure to run:

sharedlibrary libpthread

somewhere after the program has started. See the Precooked gdb Startup Scripts section for examples.

Another important thing is that whenever you want to be able to see the source code for the code you are stepping through, the library or the executable you are in must have the debug symbols present. That means that the code has to be compiled with -g option for the gcc compiler. For example if I want to set a breakpoint in /lib/libc.so, I can do that by loading:

gdb> sharedlibrary /lib/libc.so

But most likely that this library has the debug symbols stripped off, so while gdb will be able to break at the breakpoint set inside this library, you won't be able to step through the code. In order to do so, recompile the library to add the debug symbols.

If debug code in response handler you usually start the client after the server was started, when doing this a lot you may find it annoying to need to wait before the client can be started. Therefore you can use a few tricks to do it in one command. If the server starts fast you can use sleep():

```
% ddd -command=.debug-modperl-init & ; \
sleep 2 ; t/TEST -verbose -run apr/pool
```

or the Apache::Test framework's -ping=block option:

% ddd -command=.debug-modperl-init & ; \
t/TEST -verbose -run -ping=block apr/pool

which will block till the server starts responding, and only then will try to run the test.

## 1.2.4 Precooked gdb Startup Scripts

Here are a few startup scripts you can use with gdb to accomplish one of the common debugging tasks. To execute the startup script, simply run:

```
% gdb -command=.debug-script-filename
```

They can be run under gdb and any of the gdb front-ends. For example to run the scripts under ddd substitute gdb with ddd:

% ddd -command=.debug-script-filename

#### • Debugging mod\_perl Initialization

The *code/.debug-modperl-init*:

```
# This gdb startup script breaks at the modperl_hook_init() function,
# which is useful for debug things at the modperl init phase.
#
# Invoke as:
# gdb -command=.debug-modperl-init
#
# see ADJUST notes for things that may need to be adjusted
# ADJUST: the path to the httpd executable if needed
file ~/httpd/worker/bin/httpd
handle SIGPIPE nostop
handle SIGPIPE pass
set auto-solib-add 0
define myrun
    tbreak main
    break ap_run_pre_config
    # ADJUST: the httpd.conf file's path if needed
    # ADJUST: add -DPERL_USEITHREADS to debug threaded mpms
    run -d 'pwd'/t -f 'pwd'/t/conf/httpd.conf -DONE_PROCESS -DAPACHE2
    continue
end
define modperl_init
    sharedlibrary mod_perl
    b modperl_hook_init
    continue
end
define sharedap
    # ADJUST: uncomment next line to debug threaded mpms
    #sharedlibrary libpthread
    sharedlibrary apr
```

```
sharedlibrary aprutil
    #sharedlibrary mod_ssl.so
    continue
end
define sharedperl
    sharedlibrary libperl
end
# start the server and run till modperl_hook_init on start
myrun
modperl_init
# ADJUST: uncomment to reach modperl_hook_init on restart
#continue
#continue
# ADJUST: uncomment if you need to step through the code in apr libs
#sharedap
# ADJUST: uncomment if you need to step through the code in perlib
#sharedperl
```

startup script breaks at the modperl\_hook\_init() function, which is useful for debugging code at the modperl's initialization phase.

#### Debugging mod\_perl's Hooks Registeration With httpd

Similar to the previous startup script, the *code/.debug-modperl-register*:

```
# This gdb startup script allows to break at the very first invocation
# of mod_perl initialization, just after it was loaded. When the
# perl_module is loaded, and its pointer struct is added via
# ap_add_module(), the first hook that will be called is
# modperl_register_hooks().
#
# Invoke as:
# gdb -command=.debug-modperl-register
#
# see ADJUST notes for things that may need to be adjusted
define sharedap
    sharedlibrary apr
    sharedlibrary aprutil
    #sharedlibrary mod_ssl.so
end
define sharedperl
    sharedlibrary libperl
end
### Run ###
# ADJUST: the path to the httpd executable if needed
file ~/httpd/prefork/bin/httpd
handle SIGPIPE nostop
```

```
handle SIGPIPE pass
set auto-solib-add 0
tbreak main
# assuming that mod_dso is compiled in
b load module
# ADJUST: the httpd.conf file's path if needed
# ADJUST: add -DPERL_USEITHREADS to debug threaded mpms
run -d 'pwd'/t -f 'pwd'/t/conf/httpd.conf \
-DONE_PROCESS -DNO_DETACH -DAPACHE2
# skip over 'tbreak main'
continue
# In order to set the breakpoint in mod_perl.so, we need to get to
# the point where it's loaded.
#
# With static mod_perl, the bp can be set right away
#
# With DSO mod_perl, mod_dso's load_module() loads the mod_perl.so
# object and it immediately calls ap_add_module(), which calls
# modperl_register_hooks(). So if we want to bp at the latter, we need
# to stop at load_module(), set the 'bp modperl_register_hooks' and
# then continue.
# Assuming that 'LoadModule perl_module' is the first LoadModule
# directive in httpd.conf, you need just one 'continue' after
# 'ap_add_module'. If it's not the first one, you need to add as many
# 'continue' commands as the number of 'LoadModule foo' before
# perl_module, but before setting the 'ap_add_module' bp.
#
# If mod_perl is compiled statically, everything is already preloaded,
# so you can set modperl_* the breakpoints right away
b ap_add_module
continue
sharedlibrary mod_perl
b modperl_register_hooks
continue
#b modperl_hook_init
#b modperl_config_srv_create
#b modperl_startup
#b modperl_init_vhost
#b modperl_dir_config
#b modperl_cmd_load_module
#modperl_config_apply_PerlModule
# ADJUST: uncomment next line to debug threaded mpms
#sharedlibrary libpthread
# ADJUST: uncomment if you need to step through the code in apr libs
```

#sharedap

```
# ADJUST: uncomment if you need to step through the code in perlib
#sharedperl
```

startup script breaks at the modperl\_register\_hooks(), which is the very first hook called in the mod\_perl land. Therefore use this one if you need to start debugging at an even earlier entry point into mod\_perl.

Refer to the notes inside the script to adjust it for a specific httpd.conf file.

#### • Debugging mod\_perl XS Extensions

The *code/.debug-modperl-xs*:

```
# This gdb startup script breaks at the mpxs_Apache__Filter_print()
# function from the XS code, as an example how you can debug the code
# in XS extensions.
#
# Invoke as:
# gdb -command=.debug-modperl-xs
# and then run:
# t/TEST -v -run -ping=block filter/api
#
# see ADJUST notes for things that may need to be adjusted
# ADJUST: the path to the httpd executable if needed
file /home/stas/httpd/worker/bin/httpd
handle SIGPIPE nostop
handle SIGPIPE pass
set auto-solib-add 0
define myrun
    tbreak main
    break ap_run_pre_config
    # ADJUST: the httpd.conf file's path if needed
    # ADJUST: add -DPERL_USEITHREADS to debug threaded mpms
    run -d `pwd`/t -f `pwd`/t/conf/httpd.conf \
    -DONE_PROCESS -DNO_DETACH -DAPACHE2
    continue
end
define sharedap
    # ADJUST: uncomment next line to debug threaded mpms
    #sharedlibrary libpthread
    sharedlibrary apr
    sharedlibrary aprutil
    #sharedlibrary mod_ssl.so
    continue
end
define sharedperl
```

```
sharedlibrary libperl
end
define gopoll
    b apr_poll
    continue
    continue
end
define mybp
    # load Apache/Filter.so
    sharedlibrary Filter
    b mpxs_Apache__Filter_print
    # no longer needed and they just make debugging harder under threads
    disable 2
    disable 3
    continue
end
myrun
gopoll
mybp
# ADJUST: uncomment if you need to step through the code in apr libs
#sharedap
# ADJUST: uncomment if you need to step through the code in perlib
#sharedperl
```

startup script breaks at the mpxs\_Apache2\_\_Filter\_print() function implemented in *xs/Apache2/Filter/Apache2\_\_Filter.h.* This is an example of debugging code in XS Extensions. For this particular example the complete test case is:

```
% ddd -command=.debug-modperl-xs & \
t/TEST -v -run -ping=block filter/api
```

When *filter/api* test is running it calls mpxs\_Apache2\_\_Filter\_print() which is when the breakpoint is reached.

#### Debugging code in shared objects created by Inline.pm

This is not strictly related to mod\_perl, but sometimes when trying to reproduce a problem (e.g. for a p5p bug-report) outside mod\_perl, the code has to be written in C. And in certain cases, Inline can be just the right tool to do it quickly. However if you want to interactively debug the library that it creates, it might get tricky. So similar to the previous sections, here is a gdb *code/.debug-inline*:

```
# save this file as .debug and execute this as:
# gdb -command=.debug
# or if you prefer gui
# ddd -command=.debug
#
# NOTE: Adjust the path to the perl executable
# also this perl should be built with debug enabled
file /usr/bin/perl
```

```
# If you need to debug with gdb a live script and not a library, you
# are going to have a hard time to set any breakpoint in the C code.
# the workaround is force Inline to compile and load .so, by putting
# all the code in the BEGIN {} block and call Inline->init from there.
#
# you also need to prevent from Inline deleting autogenerated .xs so
# you can step through the C source code, and of course you need to
# add '-g' so .so won't be stripped of debug info
#
# here is a sample perl script that can be used with this gdb script
#
# test.pl
# #----#
# use strict;
# use warnings;
#
# BEGIN {
#
     use Inline Config =>
#
          #FORCE_BUILD => 1,
#
         CLEAN_AFTER_BUILD => 0;
#
#
     use Inline C => Config =>
#
         OPTIMIZE => '-q';
#
     use Inline C => <init;
#
#
# }
#
# my_bp();
tb main
# NOTE: adjust the name of the script that you run
run test.pl
# when Perl_runops_debug breakpoint is hit Inline will already load
# the autogenerated .so, so we can set the bp in it (that's only if
# you have run 'Inline->init' inside the BEGIN {} block
b S_run_body
continue
b Perl_runops_debug
continue
# here you set your breakpoints
b my_bp
continue
```

startup script that will save you a lot of time. All the details and a sample perl script are inside the gdb script.

# 1.3 Analyzing Dumped Core Files

When your application dies with the *Segmentation fault* error (which is generated by the SIGSEGV signal) and optionally generates a *core* file you can use gdb or a similar debugger to find out what caused the *Segmentation fault* (or a *segfault* as we often call it).

## 1.3.1 Getting Ready to Debug

In order to debug the *core* file you may need to recompile Perl and mod\_perl with debugging symbols. Usually you have to recompile only mod\_perl, but if the *core* dump happens in the *libperl.so* library and you want to see the whole backtrace, you need to recompile Perl as well. It may also occur inside httpd or 3rd party module, in which case you will need to recompile those. The following notes should help to accomplish the right thing:

• mod\_perl

rebuild mod\_perl with MP\_DEBUG=1.

% perl Makefile.PL MP\_DEBUG=1 ... % make && make test && make install

Building mod\_perl with PERL\_DEBUG=1 will:

- 1. add -g to EXTRA\_CFLAGS
- 2. turn on MP\_TRACE (tracing)
- 3. Set PERL\_DESTRUCT\_LEVEL=2
- 4. Link against libperld.so if \$Config{archlibexp}/CORE/libperld\$Config{lib\_ext} exists.

#### • httpd

If the segfault happens inside  $ap_{-}$  or  $apr_{-}$  calls, rebuild httpd with --enable-main-tainer-mode:

```
% CFLAGS="-g" ./configure --enable-maintainer-mode ...
% make && make install
```

#### • perl

If the segfault happens inside *Perl\_* calls, rebuild perl with -Doptimize='-g':

% ./Configure -Doptimize='-g' ... % make && make test && make install

Remember to recompile mod\_perl if you've recompiled perl.

#### • 3rd party perl modules

if the trace happens in one of the 3rd party perl modules, make sure to rebuild them, now that you've perl re-built with debugging flags. They will automatically pick the right compile flags from perl.

Now the software is ready for a proper debug.

### 1.3.2 Causing a SegFault

Most likely you already have the segfault situation, but sometimes you want to create one. For example sometimes you need to make sure that your system is configured to dump core files.

For that purpose you can use Debug: :DumpCore available from CPAN: http://search.cpan.org/dist/Debug-FaultAutoBT/

```
% perl -MDebug::DumpCore -eDebug::DumpCore::segv
Segmentation fault (core dumped)
```

Notice that you could use Perl's CORE::dump to achieve the same goal:

% perl -le 'dump'
Abort (core dumped)

but the generated in that case backtrace is not very useful for learning purposes. If all you want to test is whether your system is configured to dump core files then Perl's CORE : :dump will do just fine.

### 1.3.3 Getting the core File Dumped

Now let's get the *core* file dumped from within the mod\_perl server. Sometimes the program aborts abnormally via the SIGSEGV signal (*Segmentation Fault*), but no *core* file is dumped. And without the *core* file it's hard to find the cause of the problem, unless you run the program inside gdb or another debugger in first place. In order to get the *core* file, the application has to:

- 1. have the effective UID the same as real UID (the same goes for GID). Which is the case of mod\_perl unless you modify these settings in the program.
- 2. be running from a directory which at the moment of the *Segmentation fault* is writable by the process that received this signal. Notice that the program might change its current directory during its run, so it's possible that the *core* file will need to be dumped in a different directory from the one the program was originally started from.

Under Apache ServerRoot is used as the default directory. Since that directory is sually not writable by the user running Apache, it's possible to use the directive CoreDumpDirectory (available since Apache 2.0.45) to tell Apache to dump the core file elsewhere.

3. be started from a shell process with sufficient resource allocations for the *core* file to be dumped. You can override the default setting from within a shell script if the process is not started manually. In addition you can use BSD::Resource to manipulate the setting from within the code as well.

You can use ulimit for bash and limit for csh to check and adjust the resource allocation. For example inside bash, you may set the core file size to unlimited:

```
panic% ulimit -c unlimited
```

or for csh:

panic% limit coredumpsize unlimited

For example you can set an upper limit on the *core* file size to 8MB with:

panic% ulimit -c 8388608

So if the core file is bigger than 8MB it will be not created.

4. Of course you have to make sure that you have enough disk space to create a big core file (mod\_perl *core* files tend to be of a few MB in size).

Note that when you are running the program under a debugger like gdb, which traps the SIGSEGV signal, the *core* file will not be dumped. Instead it allows you to examine the program stack and other things without having the *core* file.

So let's write a simple script that uses Debug::DumpCore:

```
core_dump.pl
--------
use strict;
use warnings FATAL => 'all';
use Apache2::RequestRec ();
use Apache2::RequestIO ();
use Debug::DumpCore ();
use Cwd;
my $r = shift;
$r->content_type('text/plain');
my $dir = getcwd();
$r->print("The core should be found at $dir/core.$$\n");
$r->rflush;
Debug::DumpCore::segv();
```

In this script we load the Apache2::RequestRec, Apache2::RequestIO, Debug::DumpCore and Cwd modules, then we acquire the Apache request object and set the HTTP response header. Now we come to the real part -- we get the current working directory, print out the location of the *core* file that we are about to dump and finally we call Debug::DumpCore::segv() which dumps the *core* file.

Before we run the script we make sure that the shell sets the *core* file size to be unlimited, start the server in single server mode as a non-root user and generate a request to the script:

panic% cd /home/httpd/bin
panic% limit coredumpsize unlimited
panic% ./httpd -DONE\_PROCESS -DNO\_DETACH
 # issue a request here
Segmentation fault (core dumped)

#### Our browser prints out:

The core should be found at /home/httpd/bin/core.12345

And indeed the core file appears where we were told it will be:

```
panic% ls -l /home/httpd/bin/core.12345
-rw----- 1 stas stas 13758464 Nov 23 18:33 /home/httpd/bin/core.12345
```

As you can see it's about 14MB *core* file. Notice that mod\_perl was started as user *stas*, which had write permission for directory */home/httpd/bin*.

Notice that on certain platforms you get no PID digits appended to the core file name, so sometimes, it'll be just *core*.

### 1.3.4 Analyzing the core File

First we start gdb:

```
panic% gdb /home/httpd/bin/httpd /home/httpd/bin/core.12345
```

with the location of the mod\_perl executable and the core file as the arguments.

To see the backtrace you run the *where* or the *bt* command:

```
(gdb) bt
#0 0x407ab26c in crash_now_for_real (
    suicide_message=0x407ad300 "Cannot stand this life anymore")
    at DumpCore.xs:10
#1 0x407ab293 in crash_now (
    suicide_message=0x407ad300 "Cannot stand this life anymore",
    attempt_num=42) at DumpCore.xs:17
#2 0x407ab39b in XS_Debug__DumpCore_segv (my_perl=0x86a9298, cv=0x8d36750)
    at DumpCore.xs:26
#3 0x40540649 in Perl_pp_entersub () from .../libperl.so
...
#7 0x404530cc in modperl_callback () from .../mod_perl.so
```

Well, you can see the last commands, but our perl and mod\_perl are probably without the debug symbols. This is not the kind of trace you should send as a part of your bug report, because a lot of important information that should aid resolve the reported problem is missing.

Therefore the next step is to recompile Perl and mod\_perl (and may be Apache) with debug symbols as explained earlier in this chapter.

Now when we repeat the process of starting the server, issuing a request and getting the core file, after which we run gdb again against the executable and the dumped *core*.6789 file.

panic% gdb /home/httpd/bin/httpd /home/httpd/bin/core.6789

Now we can see the whole backtrace:

```
(gdb) bt
#0 0x407ab26c in crash_now_for_real (
   suicide_message=0x407ad300 "Cannot stand this life anymore")
   at DumpCore.xs:10
#1 0x407ab293 in crash_now (
   suicide_message=0x407ad300 "Cannot stand this life anymore",
   attempt_num=42) at DumpCore.xs:17
#2 0x407ab39b in XS_Debug__DumpCore_segv (my_perl=0x86a9298, cv=0x8d36750)
   at DumpCore.xs:26

```

That's the perfect back trace to send as a part of the bug report.

Reading the trace from bottom to top, we can see that it starts with Apache calls, followed by mod\_perl calls which end up in modperl\_callback() which calls the Perl program via Perl\_call\_sv.

Notice that in our example we knew what script has caused the Segmentation fault. In a real world the chances are that you will find the *core* file without any clue to which of handler or script has triggered it. The special *curinfo* gdb macro comes to help:

For perl enabled with threads that's:

```
define curinfo
    printf "%d:%s\n", my_perl->Tcurcop->cop_line, \
        my_perl->Tcurcop->cop_file
end
```

For a non-threaded version that's:

```
define curinfo
    printf "%d:%s\n", PL_curcop->cop_line, \
    ((XPV*)(*(XPVGV*)PL_curcop->cop_filegv->sv_any)\
    ->xgv_gp->gp_sv->sv_any)->xpv_pv
end
```

Simply past the correct version at the gdb prompt (in this example the perl is threaded):

and now we can call it:

(gdb) curinfo No symbol "my\_perl" in current context.

Oops, the function where the segfault has happened doesn't have the perl context, so we need to look at the backtrace and find the first function which accepts the my\_perl argument (this is because we use a threaded perl). In this example this is the second frame:

```
#2 0x407ab39b in XS_Debug__DumpCore_segv (my_perl=0x86a9298, cv=0x8d36750)
    at DumpCore.xs:26
```

therefore we need to go two frames up:

```
(gdb) up 2
#2 0x407ab39b in XS_Debug__DumpCore_segv (my_perl=0x86a9298, cv=0x8d36750)
    at DumpCore.xs:26
26     in DumpCore.xs
```

and now we call curinfo again:

```
gdb) curinfo
14:/home/httpd/cgi-bin/core_dump.pl
```

Et voilà, we can see that the segfault was triggered on line 14 of *core\_dump.pl*, which has the line:

```
Debug::DumpCore::segv();
```

And we are done.

These are the bits of information that are important to extract and include in your bug report in order for us to be able to reproduce and resolve a problem. In this example it was the full backtrace, the filename and line where the faulty function was called (the faulty function is Debug::DumpCore::segv()) and the actual line where the Segmentation fault occured (crash\_now\_for\_real at DumpCore.xs:10).

## 1.3.5 Analyzing the core File Automatically

If the core file(s) are found in the mod\_perl source directory, when running *t*/*REPORT* the core file back-traces will be automatically extracted and added to the report if the perl module Devel::GDB is installed.

See the function dump\_core\_file() in *Apache-Test/lib/Apache/TestReport.pm* if you want to see how it is invoked or refer to the Devel::GDB manpage.

## 1.3.6 Obtaining core Files under Solaris

There are two ways to get core files under Solaris. The first is by configuring the system to allow core dumps, the second is by stopping the process when it receives the SIGSEGV signal and "manually" obtaining the core file.

### 1.3.6.1 Configuring Solaris to Allow core Dumps

By default, Solaris 8 won't allow a setuid process to write a core file to the file system. Since apache starts as root and spawns children as 'nobody', core dumps won't produce core files unless you modify the system settings.

To see the current settings, run the coreadm command with no parameters and you'll see:

```
% coreadm
global core file pattern:
    init core file pattern: core
      global core dumps: disabled
      per-process core dumps: enabled
      global setid core dumps: disabled
      per-process setid core dumps: disabled
      global core dump logging: disabled
```

These settings are stored in the */etc/coreadm.conf* file, but you should set them with the coreadm utility. As super-user, you can run coreadm with -g to set the pattern and path for core files (you can use a few variables here) and -e to enable some of the disabled items. After setting a new pattern, enabling global, global-setid, and log, and rebooting the system (reboot is required), the new settings look like:

```
% coreadm
global core file pattern: /usr/local/apache/cores/core.%f.%p
init core file pattern: core
global core dumps: enabled
per-process core dumps: enabled
global setid core dumps: enabled
per-process setid core dumps: disabled
global core dump logging: enabled
```

Now you'll start to see core files in the designated cores directory and they will look like *core.httpd*.2222 where httpd is the name of the executable and the 2222 is the process id. The new core files will be read/write for root only to maintain some security, and you should probably do this on development systems only.

#### **1.3.6.2** Manually Obtaining core Dumps

On Solaris the following method can be used to generate a core file.

1. Use truss(1) as *root* to stop a process on a segfault:

```
panic% truss -f -l -t \!all -s \!SIGALRM -S SIGSEGV -p <pid>
```

or, to monitor all httpd processes (from bash):

```
panic% for pid in 'ps -eaf -o pid,comm | fgrep httpd | cut -d'/' -fl';
do truss -f -l -t \!all -s \!SIGALRM -S SIGSEGV -p $pid 2>&1 &
done
```

The used truss(1) options are:

- -f follow forks.
- -1 (that's an el) includes the thread-id and the pid (the pid is what we want).
- -t specifies the syscalls to trace,
- !all turns off the tracing of syscalls specified by -t
- -s specifies signals to trace and the !SIGALRM turns off the numerous alarms Apache creates.
- -S specifies signals that stop the process.
- -p is used to specify the pid.

Instead of attaching to the process, you can start it under truss(1):

panic% truss -f -l -t \!all -s \!SIGALRM -S SIGSEGV \
 /usr/local/bin/httpd -f httpd.conf 2>&1 &

2. Watch the *error\_log* file for reaped processes, as when they get SISSEGV signals. When the process is reaped it's stopped but not killed.

3. Use gcore(1) to get a *core* of stopped process or attach to it with gdb(1). For example if the process id is 662:

panic% gcore 662
gcore: core.662 dumped

Now you can load this *core* file in gdb(1).

4. kill -9 the stopped process. Kill the truss(1) processes as well, if you don't need to trap other segfaults.

Obviously, this isn't great to be doing on a production system since truss(1) stops the process after it dumps core and prevents Apache from reaping it. So, you could hit the clients/threads limit if you segfault a lot.

## **1.4 Debugging Threaded MPMs**

## 1.4.1 Useful Information from gdb Manual

Debugging programs with multiple threads: http://sources.redhat.com/gdb/current/online-docs/gdb\_5.html#SEC25

Stopping and starting multi-thread programs: http://sources.redhat.com/gdb/current/online-docs/gdb\_6.html#SEC40

## 1.4.2 libpthread

when using:

```
set auto-solib-add 0
```

make sure to:

sharedlibrary libpthread

(or whatever the shared library is used on your OS) without which you may have problems to debug the threaded mpm mod\_perl.

# 1.5 Defining and Using Custom gdb Macros

GDB provides two ways to store sequences of commands for execution as a unit: user-defined commands and command files. See: http://sources.redhat.com/gdb/current/onlinedocs/gdb\_21.html

Apache 2.0 source comes with a nice pack of macros and can be found in *httpd-2.0/.gdbinit*. To use it issue:

gdb> source /wherever/httpd-2.0/.gdbinit

Now if for example you want to dump the contents of the bucket brigade, you can do:

gdb> dump\_brigade my\_brigade

where my\_brigade is the pointer to the bucket brigade that you want to debug.

mod\_perl 1.0 has a similar file (*modperl/.gdbinit*) mainly including handy macros for dumping Perl datastructures, however it works only with non-threaded Perls. But otherwise it's useful in debugging mod\_perl 2.0 as well.

## **1.6 Expanding C Macros**

Perl, mod\_perl and httpd C code makes an extensive use of C macros, which sometimes use many other macros in their definitions, so it becomes quite a task to figure out how to figure out what a certain macro expands to, especially when the macro expands to different values in differnt environments. Luckily there are ways to automate the expansion process.

### 1.6.1 Expanding C Macros with make

The mod\_perl *Makefile*'s include a rule for macro expansions which you can find by looking for the c.i. rule. To expand all macros in a certain C file, you should run make filename.i, which will create *filename.i* with all macros expanded in it. For example to create *apr\_perlio.i* with all macros used in *apr\_perlio.c*:

```
% cd modperl-2.0/xs/APR/PerlIO
% make apr_perlio.i
```

the *apr\_perlio.i* file now lists all the macros:

```
% less apr_perlio.i
# 1 "apr_perlio.c"
# 1 "<built-in>"
#define __VERSION__ "3.1.1 (Mandrake Linux 8.3 3.1.1-0.4mdk)"
...
```

### 1.6.2 Expanding C Macros with gdb

With gcc-3.1 or higher and gdb-5.2-dev or higher you can expand macros in gdb, when you step through the code. e.g.:

```
(gdb) macro expand pTHX_
expands to: PerlInterpreter *my_perl __attribute__((unused)),
(gdb) macro expand PL_dirty
expands to: (*Perl_Tdirty_ptr(my_perl))
```

For each library that you want to use this feature with you have to compile it with:

CFLAGS="-gdwarf-2 -g3"

or whatever is appropriate for your system, refer to the gcc manpage for more info.

To compile perl with this debug feature, pass -Doptimize='-gdwarf-2 -g3' to ./Configure. For Apache run:

CFLAGS="-gdwarf-2 -g3" ./configure [...]

for mod\_perl you don't have to do anything, as it'll pick the \$Config{optimize} Perl flags automatically, if Perl is compiled with -DDEBUGGING (which is implied on most systems, if you use -Doptimize='-g' or similar.)

Notice that this will make your libraries **huge**! e.g. on Linux 2.4 Perl 5.8.0's normal *libperl.so* is about 0.8MB on linux, compiled with -Doptimize='-g' about 2.7MB and with -Doptimize='-g' about 2.7MB and with -Doptimize='-gdwarf-2 -g3' 12.5MB. httpd is also becomes about 10 times bigger with this feature enabled. *mod\_perl.so* instead of 0.2k becomes 11MB. You get the idea. Of course since you may want this only during the development/debugging, that shouldn't be a problem.

The complete details are at: http://sources.redhat.com/gdb/current/onlinedocs/gdb\_10.html#SEC69

## 1.7 Maintainers

Maintainer is the person(s) you should contact with updates, corrections and patches.
